What my "1000-well fan" assumes, and what THUMS actually is

The consequence: two different ways the shielding decays

Where this bites

My cone keeps all N wells and grows their spacing. THUMS keeps a TIGHT CORE and loses wells from it.

Both give shielding ~ (perimeter)/(count), so both decay — but the storage interval decides which regime you are in.

KEY POINT. Storage can only go in the upper, near-vertical, large-diameter cased section. That is exactly where the bundle is still tight and essentially every well is still present.

So the realistic case is probably CLOSER TO THE ISLAND-ARRAY BOUND (0.93 % loss) than to the 45° fan (12.8 %).

The price is depth: 4175 ft TVD total, and the vertical part is a fraction of that, so L_well falls well below the 5000 ft the model currently assumes — fewer MWh per well.
